

The thermodynamic limit for matter interacting with Coulomb forces and with the quantized electromagnetic field:

I. The lower bound

Abstract

The proof of the existence of the thermodynamic limit for electrons and nuclei interacting via the Coulomb potential, in the framework of non-relativistic quantum mechanics, was accomplished decades ago. This result did not take account of interactions caused by magnetic fields, however, (the spin-spin interaction, in particular) or of the quantized nature of the electromagnetic field. Recent progress has made it possible to undertake such a proof in the context of non-relativistic QED. This paper contains one part of such a proof by giving a lower bound to the free energy which is proportional to the number of particles and which takes account of the fact that the field, unlike the particles, is never confined to a finite volume. In the earlier proof the lower bound was a ‘two line’ corollary of the ‘stability of matter’. In QED the proof is much more complicated.

1 Introduction

Some years ago the problem of proving the existence of the thermodynamic limit for electrons, nuclei and other particles interacting via Coulomb forces was settled in the context of the non-relativistic Schrödinger equation [10]. The key ingredients in this proof, in broad outline, were:

a) The stability of matter of the second kind [3] (i.e., a lower bound on the ground state energy proportional to the number of particles), which led to an upper bound on the partition function $\mathcal{Z}$, and hence a domain independent lower bound on f , the free energy per particle.

b) A rigorous version of screening together with a variational argument for a lower bound on $\mathcal{Z}$, which led to the fact that f could only decrease (with the density ρ and inverse temperature $\beta = 1/k_B T$ fixed) as the size of the domain Ω containing the particles increases. Charge neutrality is needed for this monotonicity of f (but not for the lower bound). Since f is bounded, this monotonicity guarantees that f has a limit as $|\Omega|$, the volume of Ω , tends to infinity.

Since then much progress has been made in understanding non-relativistic quantum electrodynamics (QED) and it seems appropriate now to try to extend the proof of the thermodynamic limit to the QED case. This is not just an idle exercise, for several new matters of a physical nature, as well as a mathematical nature, arise. Among these is the fact this model completely takes account of everything that we know about low energy physics, except for the hyperfine interaction (for which nuclear physics is necessary, as we explain below), and except for the fact that the dynamics of the particles (but not the electromagnetic field) is non-relativistic. Indeed, no completely satisfactory relativistic Hamiltonian is presently available and, therefore, the fully relativistic generalization will have to await further developments. Another problem, which is yet to be resolved, is the renormalization of physical parameters in order to deal with the infinities that arise as Λ , the ultraviolet cutoff on the electromagnetic field, tends to infinity.

Otherwise, the theory is potentially complete, as we said, and an example of this completeness is that it is not necessary to exclude the spin-spin inter-electron magnetic interaction, as in [10]. The usual non-QED approximation is to mimic the interaction by a r^{-3} spin-dependent potential, which cannot possibly be stable, and which is, therefore, omitted from discussion unless a hard core interaction is introduced to stabilize it. In contrast, in a full theory in which the magnetic field $B(x)$ is a dynamical variable and the particles interact with the field via a $\sigma \cdot B(x)$ term (but without any explicit spin-spin interaction) is perfectly well behaved and stable and has all the right physics in the classical limit.

(We note in passing that stability of matter requires more than just the field energy to stabilize the $\sigma \cdot B(x)$ terms. It also requires the ‘kinetic’ energy terms $(p + eA(x)/c)^2$ to control the $\sigma \cdot B(x)$ terms, and thereby stabilize the system. In other words, the terms $p \cdot A(x) + A(x)^2$ are essential for understanding the interaction of particles with each other at small distances; the dipole-dipole approximation while correct at large distances, is certainly inadequate at short distances.)

Another major difference between the Schrödinger and the QED theories of the thermodynamic limit is the necessity of treating the thermodynamics of the field correctly. In 1900 Planck [14] gave us the energy density of the pure electromagnetic field at temperature T , which implies that the field cannot be confined to the container Ω without invoking artificial constraints. As we shall explain in detail later, this requires us first to take a limit in which the size of the universe $\mathcal{U}$ tends to infinity (after subtracting the enormous pure Planck free energy) and afterward to take the limit $|\Omega| \rightarrow \infty$. Obviously, the subtraction has to be done carefully and that is an exercise in itself.

In this paper we consider topic a) above — the upper bound on $\mathcal{Z}$ or lower bound on f (after taking the double limit, of course). We shall reserve topic b) for later. In the previous work [10] the upper bound required only a few lines, as we shall explain below, but our QED setting presents significant difficulties that have to be overcome. While the analog of the Dyson-Lenard lower bound on the energy [3] is known for this QED case (see [16, 2]), it is far from sufficient for obtaining the upper bound on $\mathcal{Z}$.

2 Basic Definitions

There are N electrons with mass m and charge $-e$. These are fermions with spin $1/2$. There are also K nuclei with several kinds of masses Mm (with $M > 1800$ in nature), positive charges Ze and statistics (Bose or Fermi) but, in order to simplify the notation, we shall assume only one species with charge Ze and mass Mm . The generalization to many species is trivial, the only significant point being that all the nuclei have a Z -value not greater than some fixed number Z . We also assume that the nuclei are point charges, the generalization to smeared out nuclei being a trivial generalization.

The arena in which the particles reside is a large region $\Omega \subset \mathbb{R}^3$, of unspecified shape for the present purposes, and volume $|\Omega|$. It is a subset of an even larger domain $\mathcal{U}$, the ‘universe’ which, for simplicity we take to be a cube of side length L . The boundary conditions of the EM field on $\partial\mathcal{U}$ is, presumably, of no importance, so we take periodic boundary conditions

for simplicity (although it has to be noted that changing the boundary conditions on the $\partial\mathcal{U}$ changes the total energy (when the temperature is not zero) by an amount far greater than the energy contained in Ω). One could dispense with the universe $\mathcal{U}$ by confining the EM field to the box Ω , but this would be questionable physically and we shall not do so here. The two limits (i.e., with or without the confinement of the field to Ω) would be expected to yield the same average energy density in the thermodynamic limit, but we prefer to take nothing for granted.

The Hilbert space is

$$\mathcal{H} = \mathcal{H}_{\text{electron}} \otimes \mathcal{H}_{\text{nuclei}} \otimes \mathcal{F} , \quad (2.1)$$

where $\mathcal{F}$ is the photon Fock space in $\mathcal{U}$ and $\mathcal{H}_{\text{electron}}$ is the antisymmetric tensor product $\wedge_{i=1}^N L^2(\Omega; \mathbb{C}^2)$ appropriate for spin 1/2 fermions. Likewise, $\mathcal{H}_{\text{nuclei}}$ is an antisymmetric tensor product of $\wedge_{j=1}^K L^2(\Omega; \mathbb{C}^2)$ (for fermions) or a symmetric tensor product of K $L^2(\Omega)$ spaces (for bosons) or a mixture of them in the case of several species. A vector in $\mathcal{H}$ is a function of N electron coordinates and spins $x_1, \dots, x_N; \sigma_1, \dots, \sigma_N$ and K nuclear coordinates (and possibly spins if they are fermions) $R_1, \dots, R_K$ with values in $\mathcal{F}$, i.e., it is a vector in $\mathcal{F}$ that depends on the particle coordinates and spins.

Units: The physical units we shall employ here are $2mc^2$ for the energy and $\lambda_c/2$ for the length (where $\lambda_c = \hbar/mc$ is the electron Compton wavelength). The dimensionless fine structure constant is $\alpha = e^2/\hbar c$ ($= 1/137$ in nature). The electron charge is then $-\sqrt{\alpha}$ and the nuclear charge is $Z\sqrt{\alpha}$.

The total Hamiltonian is

$$H = T + \alpha V_c + H_f , \quad (2.2)$$

where the three terms are the kinetic energy of the particles, the Coulomb potential energy and the quantized field energy, which will be explained in detail presently.

The partition function is given by the trace $\mathcal{Z} = \text{Tr} \exp[-\beta H]$ and the pure-field partition function is given by $\mathcal{Z}_0 = \text{Tr} \exp[-\beta H_f]$, with $\beta = 1/k_B T$. We are interested in the free energy per unit volume

$$f = -k_B T \lim_{|\Omega| \rightarrow \infty} \lim_{L \rightarrow \infty} \frac{1}{|\Omega|} \{ \log \mathcal{Z} - \log \mathcal{Z}_0 \} , \quad (2.3)$$

with the understanding that we set $N = \rho_{\text{electron}} \cdot |\Omega|$ and $K = \rho_{\text{nucleus}} \cdot |\Omega|$ for some fixed densities ρ_{electron} and ρ_{nucleus} . We denote them, collectively, simply as ρ . Charge neutrality is not assumed.

Our goal here is to derive a lower bound to f . We do not claim to prove that the limits in (2.3) exist. For the present purpose they are interpreted as $\limsup$ instead of $\lim$.

We now define the various energies in detail. First, the kinetic energies (in units of $2mc^2$).

$$T = T^{\text{el}} + T^{\text{nuc}} = \sum_{i=1}^N T_i^P(A) + \frac{1}{M} \sum_{j=1}^K T_j(-ZA) . \quad (2.4)$$

The electron kinetic energy operator for each electron is the Pauli operator

$$T^P(A) = (\sigma \cdot (p + \sqrt{\alpha} A(x)))^2 = (p + \sqrt{\alpha} A(x))^2 + \sqrt{\alpha} \sigma \cdot B(x) , \quad (2.5)$$

which is appropriate for a spin 1/2 fermion in the presence of a magnetic vector potential $A(x)$ and magnetic field $B(x) = \text{curl}A(x)$. The operator p is given (in our units) by $p = -i\nabla$. The subscript i in $T_i^P(A)$ in (2.4) indicates that this operator acts on the coordinates of electron i and the x in (2.4) is then x_i . Note that in this model the g -factor of the electron is 2. If it were greater than this we would be in serious trouble because then the stability of matter would not hold [5]. (Strictly speaking the result in [5] about $|g| > 2$ holds only for classical fields without UV cutoff. With a cutoff one expects stability of the first kind, i.e., a finite ground state energy, but not stability of the second kind, i.e., a lower bound that is proportional to the number of particles. Although well known QED calculations say that the renormalized, effective g -factor exceeds 2, QED theory always starts with 2, otherwise the theory would not be renormalizable [19].)

Since the nuclear charge is $+Z\sqrt{\alpha}$ we have $-ZA$ in (2.4). The kinetic energy operator in (2.4) omits the $\sigma \cdot B(x)$ term, i.e., it is

$$T_j(A) = (p_j + \sqrt{\alpha} A(R_j))^2 , \quad (2.6)$$

in which R_j is the coordinate of the j^{th} nucleus. A nucleus can have a magnetic moment, even if its charge is zero (the neutron) but it often has a g -factor much larger than 2 (e.g, $g \approx 5.5$ for a proton).

A conventional ‘physical argument’ might be that since the magnetic moment is inversely proportional to the mass, the contribution of the magnetic energy to the total energy is small. As mentioned before, however, the inclusion of a dipole-dipole interaction has disastrous consequences, no matter how small the coupling is. It follows that to include this magnetic interaction, and hence to include the hyperfine interaction, we would have to take explicit account of the nuclear magnetic form factor. In essence this really means thinking of the nuclei as a compound system of quarks. The interaction of quarks with the EM field will surely have diamagnetic components. The effects of the nuclear structure, which would add a self-energy proportional to K , could be included, but we prefer to avoid this discussion here.

We use the Coulomb gauge to describe the EM field and its energy. In this gauge only the magnetic field is a dynamical variable, i.e., the curl-free part of the electric field is not an independent dynamical variable, for it is determined by the particle coordinates and Coulomb's law. This choice of gauge is essential because, as we have said elsewhere [8, 11], it is the only gauge in which the correct physical EM interactions (including the spin-spin magnetic interaction) can be obtained by a minimization principle.

The field energy (in our units) is

$$H_f = \sum_k \sum_{j=1}^3 |k| a_j^*(k) a_j(k) , \quad (2.7)$$

where the three operators $\mathbf{a}(k) = (a_1(k), a_2(k), a_3(k))$ are boson annihilation operators of momentum k satisfying the canonical commutation relations $[a_i(q), a_j^*(k)] = \delta_{i,j} \delta_{q,k}$, etc. (We are using the convention of three-component quantized fields introduced in [11], which means that we have to subtract the Planck background energy in (2.3) for *three* modes instead of two. The advantage of this formalism is that we do not have to introduce the k -dependent classical polarization vectors $\varepsilon_\lambda(k)$ to insure the 'divergence-free condition' on the vector potential $A(x)$.) The k sum in (2.7) is over k 's of the form $k = (2\pi/L)(n_1, n_2, n_3)$ with integer n_i , but $k = 0$ is excluded. As $L \rightarrow \infty$, $(2\pi/L)^3$ times the sum over k becomes an integral $\int_{\mathbb{R}^3}$, but for a finite L we have to do the sum carefully in order to get the correct cancellation.

The vector potential is obtained by first defining the vector field

$$C(x) = \frac{1}{2\pi} \left(\frac{2\pi}{L} \right)^{3/2} \sum_k \chi_\Lambda(k) \frac{1}{|k|^{3/2}} [\mathbf{a}(k) e^{ik \cdot x} - \mathbf{a}^*(k) e^{-ik \cdot x}] , \quad (2.8)$$

where $\hat{\chi}_\Lambda \leq 1$ is a radial function that vanishes outside a ball of radius Λ . Then

$$A(x) = i \operatorname{curl} C(x) .$$

In the Coulomb gauge the electrostatic energy αV_c is given by a simple coordinate-dependent potential

$$V_c = \sum_{1 \leq i < j \leq N} \frac{1}{|x_i - x_j|} + Z^2 \sum_{1 \leq i < j \leq K} \frac{1}{|R_i - R_j|} - Z \sum_{1 \leq i \leq N} \sum_{1 \leq j \leq K} \frac{1}{|x_i - R_j|} . \quad (2.9)$$

Having introduced the free energy and its component parts we can now discuss the physical and mathematical problems addressed in this paper, namely the difference between the QED problem and the non-QED problem in [10].

The non-QED problem: In this case there is no need to introduce the ‘universe’ $\mathcal{U}$, the field energy H_f or to take the double limit in (2.3) because there is no particle-field interaction via the field $A(x)$. To obtain a lower bound to f one simply writes [10, Theorem 2.2] $H = \tilde{H}_1 + \tilde{H}_2$ with

$$\tilde{H}_1 = \frac{1}{2}T + \alpha V_c \quad \tilde{H}_2 = \frac{1}{2}T . \quad (2.10)$$

One then bounds $\tilde{H}_1$ from below by $-c(N + K)$, where c is a universal constant, which follows from the stability of matter bound. (The constant c changes when we replace T by $T/2$ but it is always finite.) Then, we can bound f by

$$f \geq -c(\rho_{\text{electron}} + \rho_{\text{nucleus}}) - k_B T \lim_{\Omega \rightarrow \infty} |\Omega|^{-1} \log \text{Tr} e^{-\beta T/2} . \quad (2.11)$$

The latter trace is just the partition function of an ideal gas of twice the mass and has, as the elementary textbooks tell us, a finite f (which can be easily bounded from below by a shape independent f). Thus, a satisfactory lower bound to f is a ‘two-line argument’ in this case.

The QED problem: Several points have to be considered.

1. The precise cancellation of the background Planck field energy, which is enormously greater than f , has to be done carefully.
2. We know from earlier work [16] that the stability of matter does not hold for the Pauli kinetic energy unless the field energy is added to the Hamiltonian. This implies that we must somehow borrow some field energy to stabilize the Pauli analog of H_1 above, but not too much to spoil the delicate cancellation in item 1. The situation with the quantized field energy H_f in place of a classical field energy $\int_{\mathbb{R}^3} B(x)^2 dx / 8\pi$ is even more delicate; this extension was first made in [2] using the results in [16]. The idea in [2] is to replace the field energy term by one that is localized near the nuclei. Our approach will be somewhat different and will only involve localization of the electrons, in a manner reminiscent of the original Dyson-Lenard proof [3] of stability of matter. (However, if we do not care that our lower bound for f does not go to zero as $\rho \rightarrow 0$ then localization is not needed – see section 5.) In any event, the stability of matter using the Pauli operator and H_f requires a bound on α and $Z\alpha^2$, when there is no ultraviolet cutoff; this is a feature not encountered in the non-QED problem. We shall prove that f is bounded below (for all Λ if $\alpha \leq 1/98$ and if $Z\alpha^2 < 1/468$ (corresponding to $Z \leq 39$ for $\alpha = 1/137$). These bounds can certainly be improved, with some effort, but we shall not attempt to do so.

3. The lower bound on f should be shown to have a classical limit as the nuclear mass M tends to infinity, independent of the statistics of the nuclei. ‘Classical’ means that the dependence of f on M has the form $f \sim K \rho_{\text{nucleus}} k_B T \left[\frac{3}{2} \log(\beta/M) + \log \rho_{\text{nucleus}} - 1 \right]$. This would coincide with the experimental observation that the nuclei may as well be considered to be fixed in space.
4. While an infrared cutoff is *not* needed for our considerations, the ultraviolet cutoff Λ is essential. One would like to take the limit $\Lambda \rightarrow \infty$ after a renormalization of the electron mass and possibly its charge. At present, it is not known how to carry out this program, although some primitive steps were taken in [12]. In any case, in order to show that $\Lambda \rightarrow \infty$ limit can be taken for the thermodynamics it is appropriate and necessary to show the following. There are three functions $f_\infty(\beta, \rho, Z)$, $g_{\text{nucleus}}(\Lambda, Z)$ and $g_{\text{electron}}(\Lambda)$ such that the free energy per unit volume, $f(\beta, \rho, Z, \Lambda)$, which depends on all four parameters, can be decomposed as

$$f(\beta, \rho, Z, \Lambda) = f_\infty(\beta, \rho, Z) + g_{\text{electron}}(\Lambda) \rho_{\text{electron}} + g_{\text{nucleus}}(\Lambda, Z) \rho_{\text{nucleus}} . \quad (2.12)$$

We make the additional requirement that $f_\infty(\beta, \rho, Z) \propto \rho$ as $\rho \rightarrow 0$. With no particles there should be no free energy. (It is also physically desirable that the self-energy term $g_{\text{electron}}(\Lambda)$ should be large and positive when Λ is large. We succeed only partially in this respect, as discussed in the remark following Theorem 3.1.)

In this paper a lower bound of the form (2.12) will be derived and it will have the indicated properties. This is done in section 3 with help from section 4 and the Appendices

If we forego the property that $f_\infty(\beta, \rho, Z) \propto \rho$ as $\rho \rightarrow 0$ then it is significantly easier to obtain a lower bound of the form (2.12). This is shown in section 5.

3 Main Theorem and Proof

In this section we show how to decompose H in a manner reminiscent of (2.10) and how to use this to prove a lower bound of the form (2.12), under the assumption that certain inequalities hold. These inequalities will be proved in subsequent sections and appendices. In the following $\mathcal{Z}_{\text{nucleus}}$ is the partition function of non-interacting bosons of mass Mm . As $M \rightarrow \infty$ this partition function tends to the classical partition function if $T > 0$. This was one of our requirements in item 3 in section 2.

Thus, we shall prove the following in this section.

THEOREM 3.1 (Lower bound on f). *Assume that $\alpha < 1/98$ and $Z\alpha^2 < (\frac{39}{40})(\frac{1}{468})$. (This means $Z \leq 39$ when $\alpha = 1/137$.) Then (2.11) holds with*

$$f_\infty(\beta, \rho, Z) > -kT \{ \rho_{\text{electron}} \ln 2 + \rho_{\text{electron}} \ln(\rho_{\text{electron}}) - \rho_{\text{electron}} \} \\ - kT \rho_{\text{electron}} \ln(8\pi(kT)^3 C_3^{-3}) + f_{\text{nucleus}}(\beta, \rho_{\text{nucleus}}) , \quad (3.1)$$

$$g_{\text{electron}}(\Lambda) > -(128 + 0.0032) \Lambda^{8/5} - \left(\frac{1}{149\alpha} \right)^2 - \left(\frac{4\pi}{3} \right) (468)(40) \Lambda^{3/5}, \quad (3.2)$$

$$g_{\text{nucleus}}(\Lambda, Z) \geq 0 , \quad (3.3)$$

where f_{nucleus} is the free energy per unit volume for non-interacting bosonic nuclei of mass mM and

$$C_3\alpha = \frac{1}{149} - \alpha^2 \max\{64.5, \pi Z\} - \frac{1}{149} \exp \left\{ \frac{-468}{1 - 468Z\alpha^2} \right\} \quad (3.4)$$

See equation (3.39) for a more general expression.

REMARK: The bounds (3.3) on $g_{\text{electron}}(\Lambda)$ and $g_{\text{nucleus}}(\Lambda, Z)$ should actually be large and positive owing to the self-energy of the charged particles. In [13] we showed that the dependence of this self-energy on Λ is somewhere between $\Lambda^{3/2}$ and $\Lambda^{12/7}$ and we conjectured that $\Lambda^{12/7}$ was the correct dependence. If $\Lambda^{12/7}$ is, indeed, correct then we could easily invoke the methods of [13] and add a term proportional to $\Lambda^{12/7}$ to $g_{\text{electron}}(\Lambda)$, which would dominate the $\Lambda^{8/5}$ term and thereby leave us with the desired large positive value for $g_{\text{electron}}(\Lambda)$. On the other hand, if $\Lambda^{3/2}$ is correct then adding $\Lambda^{3/2}$ to $g_{\text{electron}}(\Lambda)$ will not produce a positive self-energy (for large Λ , of course). Since the $\Lambda^{3/2} - \Lambda^{12/7}$ question is not yet settled, we shall not burden this paper further with the question of the sign of the self-energy. We note in passing, however, that the simpler theorem in section 5 has a huge negative Λ dependence (i.e., $-\Lambda^4$), which cannot be compensated even by $\Lambda^{12/7}$.

Proof. The first step is to localize the electrons. Decompose Ω into disjoint cubes of side-length Λ^{-s} . There will be approximately $|\Omega| \Lambda^{3s}$ of these cubes. For each cube γ_ℓ we take a smooth function ϕ_ℓ centered on γ_ℓ , whose support is in a cube Γ_l of twice the side length and in such a way that

$$\sum_{\ell} \phi_\ell(x)^2 = 1 \quad \text{for all } x \in \Omega . \quad (3.5)$$

We can and do require that $|\nabla \phi_\ell(x)| \leq 4\Lambda^s$.

It is easily seen that for each point x there can be at most 8 distinct values of ℓ for which $\phi_\ell(x) \neq 0$, and hence, by the standard IMS localization formula,

$$T^P(A) = \sum_{\ell} \phi_\ell(x) T^P(A) \phi_\ell(x) - \sum_{\ell} |\nabla \phi_\ell(x)|^2 \geq \sum_{\ell} \phi_\ell(x) T^P(A) \phi_\ell(x) - 128\Lambda^{2s} . \quad (3.6)$$

for all $A(x)$. By applying this to each term in T^{electron} , and recalling (3.5), we obtain the inequality

$$T^{\text{electron}} \geq \sum_I \Phi_I T^{\text{electron}} \Phi_I - 128N\Lambda^{2s} , \quad (3.7)$$

where $I = (\ell_1, \dots, \ell_N)$ is a multi-index and $\Phi_I(\underline{X}) = \Phi_I(x_1, \dots, x_N) = \phi_{\ell_1}(x_1) \cdots \phi_{\ell_N}(x_N)$ is a product function, which satisfies $\sum_I \Phi_I(\underline{X})^2 = 1$ when $\underline{X} \in \Omega^N$. Here, $\underline{X} = (x_1, x_2, \dots, x_N)$ collectively denotes the N electron coordinates; similarly, $\underline{R} = (R_1, R_2, \dots, R_K)$ denotes the K coordinates of the nuclei.

Armed with this localization, and recalling (3.5), we can write (for an arbitrary constant $C_1 > 0$)

$$\begin{aligned} T^{\text{electron}} &\geq \sum_I \Phi_I(\underline{X}) \sum_{i=1}^N \{T_i^P(A) - C_1|p_i + \sqrt{\alpha}A(x_i)|\} \Phi_I(\underline{X}) \\ &\quad + \sum_I \Phi_I(\underline{X}) \sum_{i=1}^N C_1|p_i + A(x_i)| \Phi_I(\underline{X}) - 128N\Lambda^{2s} , \end{aligned} \quad (3.8)$$

and hence our Hamiltonian is bounded below as

$$H \geq H_2 := \sum_I \Phi_I(\underline{X}) [H^{\text{rad}} + H^{\text{rel}}] \Phi_I(\underline{X}) - 128N\Lambda^{2s} , \quad (3.9)$$

where

$$H^{\text{rad}} = \sum_{i=1}^N \{T_i^P(A) - C_1|p_i + \sqrt{\alpha}A(x_i)|\} + H_f \quad (3.10)$$

$$H^{\text{rel}} = T^{\text{nucleus}} + C_1 \sum_{i=1}^N |p_i + \sqrt{\alpha}A(x_i)| + \alpha V_c . \quad (3.11)$$

The superscript ‘rel’ is meant to suggest that (3.11) is a Hamiltonian of relativistic-like electrons and non-relativistic nuclei. Note that $\sum_I \Phi_I(\underline{X}) H_f \Phi_I(\underline{X}) = H_f$ since H_f does not depend on the electron coordinates $\underline{X}$.

The reason for adding and subtracting the ‘relativistic’ kinetic energy operator $|p + \sqrt{\alpha}A(x)|$ is that $\text{Tr exp}\{-T^P(A)\}$ is not bounded independent of the vector field A , but $\text{Tr exp}\{-|p + \sqrt{\alpha}A(x)|\}$ is uniformly bounded.

In sect. 4, Lemma 4.1, we shall show that the sum appearing in (3.10) is bounded below by

$$-\frac{16\alpha C_1 \mathcal{L}}{3\sqrt{3}} \sum_I \Phi_I(\underline{X})^2 \int_{\mathbb{R}^3} B(y)^2 W_I(y) dy - NC_1^2, \quad (3.12)$$

where W_I , given in (4.2), is a sum of characteristic functions of subsets of Ω whose total volume is at most $8N\Lambda^{-3s}$. This function has the following properties for each I :

$$\int_{\mathbb{R}^3} W_I(y) dy \leq 8N\Lambda^{-3s}, \quad W_I(y) \leq 8. \quad (3.13)$$

The constant $\mathcal{L}$ stems from the application of a Lieb-Thirring inequality and it is bounded above by 0.06003.

If $D(y)$ is the (vector) operator obtained from the $\mathbf{a}$ part of (2.8), namely

$$D(y) = \frac{i}{2\pi} \text{curl} \text{curl} \left(\frac{2\pi}{L} \right)^{3/2} \sum_k \chi_\Lambda(k) \frac{1}{|k|^{3/2}} \mathbf{a}(k) e^{ik \cdot y} \quad (3.14)$$

$$= \frac{1}{2\pi} \left(\frac{2\pi}{L} \right)^{3/2} \sum_k \chi_\Lambda(k) \frac{1}{|k|^{3/2}} e^{ik \cdot y} [k^2 \mathbf{a}(k) - (k \cdot \mathbf{a}(k))k], \quad (3.15)$$

then $B(y) = D(y) + D^*(y)$ and Schwarz's inequality leads to

$$B(y)^2 \leq 4D^*(y)D(y) + 2[D(y), D(y)^*], \quad (3.16)$$

which then implies that

$$\int_{\mathbb{R}^3} B(y)^2 W_I(y) dy \leq 4 \int_{\Omega} D^*(y) \cdot D(y) W_I(y) dy + \frac{8}{\pi} \Lambda^{4-3s} N. \quad (3.17)$$

Altogether, (3.12) and the definition of H^{rad} and H^{rel} lead to the lower bound

$$H \geq H_2 \geq H_3 := \sum_I \Phi_I(\underline{X}) [H_1^{\text{rad}} + H^{\text{rel}}] \Phi_I(\underline{X}) - \left[128\Lambda^{2s} + C_1^2 + \frac{128\alpha C_1 \mathcal{L}}{3\sqrt{3}\pi} \Lambda^{4-3s} \right] N, \quad (3.18)$$

where H_1^{rad} is a replacement for H^{rad} given by

$$H_1^{\text{rad}} = H_f - \frac{64\alpha C_1 \mathcal{L}}{3\sqrt{3}} \sum_I \Phi_I(\underline{X})^2 \int_{\mathbb{R}^3} D^*(y) D(y) W_I(y) dy. \quad (3.19)$$

In summary, our lower bound Hamiltonian H_3 contains three parts: A constant proportional to N , a perturbed field energy $\sum_I \Phi_I H_1^{\text{rad}} \Phi_I$, and the Hamiltonian $\sum_I \Phi_I H^{\text{rel}} \Phi_I$ of 'relativistic' electrons and non-relativistic nuclei. Their definitions depend on a constant $C_1 > 0$ and on the parameter s , which defines the electron localization. These will be chosen later.

Our final goal is to prove the following upper bound on $\text{Tr} \exp\{-\beta H_3\}$, which will then complete the proof of Theorem 3.1.

LEMMA 3.2.

$$\begin{aligned} \mathrm{Tr} e^{-\beta H_3} &\leq \mathcal{Z}_{\text{nucleus}}(K) \frac{1}{N!} \left[\int_{\mathbb{R}^3} e^{-\beta C_3 |p|} dp \right]^N \mathrm{Tr}_{\mathcal{F}} e^{-\beta H_f} \times \\ &\quad \exp \left\{ \beta N (128 \Lambda^{2s} + C_1^2 + \frac{128 \alpha C_1 \mathcal{L}}{3\sqrt{3}\pi} \Lambda^{4-3s} + \frac{4\pi}{3} |\ln(1-\varepsilon)| \Lambda^{3-3s}) \right\} , \end{aligned} \quad (3.20)$$

where $\mathcal{Z}_{\text{nucleus}}(K)$ is the partition function of K non-interacting bosons of mass M (even if some of the nuclei happen to be fermions). The number ε (assumed to be < 1 , see (C.10)) is

$$\varepsilon = \frac{4096 \pi}{3\sqrt{3}} \alpha C_1 \mathcal{L}. \quad (3.21)$$

Proof. First, we dispose of the localization function $\Phi(\underline{X})$ that appear in the Hamiltonian H_3 of (3.18). By Lemma B.1 in Appendix B, and the fact that $\sum_I \Phi_I(\underline{X})^2 = I = \text{identity operator on our Hilbert space (2.1)}$,

$$\mathrm{Tr} e^{-\beta H_3} \leq \mathrm{Tr} e^{-\beta(H_1^{\text{rad}} + H^{\text{rel}})} \exp \left\{ \beta N (128 \Lambda^{2s} + C_1^2 + \frac{128 \alpha C_1 \mathcal{L}}{3\sqrt{3}\pi} \Lambda^{4-3s}) \right\} . \quad (3.22)$$

Next, we introduce another constant $0 < C_3 < C_1$, and write

$$H^{\text{rel}} = T^{\text{nucleus}} + C_3 \sum_{i=1}^N |p_i + \sqrt{\alpha} A(x_i)| + \sum_{i=1}^N (C_1 - C_3) |p_i + \sqrt{\alpha} A(x_i)| + \alpha V_c . \quad (3.23)$$

Using the result of [17], as stated in [16] (see also [15]), the last two terms, taken together, are positive as an operator on the tensor product space of the nuclei and the spin 1/2 electrons provided that

$$C_1 - C_3 \geq \max \left\{ \frac{2}{0.032}, \pi Z \right\} \alpha . \quad (3.24)$$

If (3.24) is true then

$$H^{\text{rel}} \geq H_1^{\text{rel}} := T^{\text{nucleus}} + C_3 \sum_{i=1}^N |p_i + \sqrt{\alpha} A(x_i)| . \quad (3.25)$$

Using this and the Golden-Thompson inequality

$$\mathrm{Tr} e^{-\beta(H_1^{\text{rad}} + H^{\text{rel}})} \leq \mathrm{Tr} e^{-\beta(H_1^{\text{rad}} + H_1^{\text{rel}})} \leq \mathrm{Tr} \left(e^{-\beta H_1^{\text{rad}}} e^{-\beta H_1^{\text{rel}}} \right) . \quad (3.26)$$

We evaluate the trace in the Schrödinger representation in which the field A is a c-number field and the trace is just integration over this classical field. This is a rigorous technique in quantum field theory and we explain it in some detail in Appendix A. We

then use the fact that for a fixed classical field $A(y)$ the operator $e^{-\beta H_1^{\text{rel}}}$ has a kernel $\exp\{-\beta H_1^{\text{rel}}\}(\underline{X}, \underline{R}; \underline{X}, \underline{R})$, and we can write the right side of (3.26) as

$$\text{Tr} e^{-\beta H_1^{\text{rel}}} e^{-\beta H_1^{\text{rad}}} = 2^N \int \mathcal{D}(A) \int d\underline{X} d\underline{R} e^{-\beta H_1^{\text{rel}}(A)}(\underline{X}, \underline{R}, \underline{\cdot}; \underline{X}, \underline{R}, \underline{\cdot}) \langle A | e^{-\beta H_1^{\text{rad}}} | A \rangle(\underline{X}), \quad (3.27)$$

where the factor 2^N comes from the electron spins. (Note that H_3 has no electron-spin dependence.) There might be a factor for nuclear spins, but we shall ignore this subtlety in order to keep the notation simple. In any case it can be absorbed in the factor $\mathcal{Z}_{\text{nucleus}}(K)$.

Obviously, the matrix element $e^{-\beta H_1^{\text{rel}}(A)}(\underline{X}, \underline{R}; \underline{X}, \underline{R})$ is the product of a factor depending on the nuclear coordinates $\underline{R}$ and a factor depending on the electron coordinates $\underline{X}$. Each of these factors is an (A -dependent) partition function of non-interacting particles. The former depends on the statistics of the nuclei. If the nuclei are bosons $e^{-\beta H_1^{\text{rel}}(A)}(\underline{X}, \underline{R}; \underline{X}, \underline{R})$ can be written as

$$\frac{1}{K!} \text{per} \left(\exp\left\{-\frac{\beta}{M}(p - Z\sqrt{\alpha}A(x))^2\right\}(R_j, R_k)\right) \times \frac{1}{N!} \det \left(\exp\{-\beta C_3|p + \sqrt{\alpha}A(x)|\}(x_i, x_j)\right), \quad (3.28)$$

where per indicates the permanent of the $K \times K$ matrix (indexed by $j, k \in \{1, \dots, K\}$) and $\det$ the determinant of the $N \times N$ matrix (indexed by $i, j \in \{1, \dots, N\}$). If the nuclei are also fermions or a mixture of fermions and bosons we have to replace the permanent above by the corresponding symmetrized or antisymmetrized product, i.e., permanent for a boson species or determinant for a fermion species.

For our purpose here, namely an upper bound, we may assume from now on that all the nuclei are bosons. The reason is that the $K \times K$ matrix above is positive definite, and so is the $N \times N$ matrix. It is a fact that the determinant of a positive definite matrix is not greater than the permanent. Indeed, the determinant is less than or equal to the product of the diagonal entries while the permanent is greater than or equal to the same product. (See ([9]).) Since $\langle A | e^{-\beta H_1^{\text{rad}}} | A \rangle$ is positive, we can use this upper bound on the determinant to obtain the following upper bound to the right side of (3.27)

$$\int \mathcal{D}(A) \int d\underline{X} d\underline{R} \frac{1}{K!} \text{per} \left(e^{-\frac{\beta}{M}(p - Z\sqrt{\alpha}A(x))^2}(R_j, R_k)\right) \times \frac{1}{N!} \prod_{i=1}^N \left(e^{-\beta C_3|p + \sqrt{\alpha}A(x)|}(x_i, x_i)\right) \times \langle A | e^{-\beta H_1^{\text{rad}}} | A \rangle(\underline{X}), \quad (3.29)$$

Since all the factors in (3.29) are positive, we can appeal to the diamagnetic inequality and delete the field A from the second factor. (The diamagnetic inequality is well known

and states that $\exp[-\beta|p + \sqrt{\alpha}A(x)|^2](x_i, x_j) \leq \exp[-\beta|p|^2](x_i, x_j)$, which follows from the Feynman-Kac representation; it is also true for $\exp[-\beta|p + \sqrt{\alpha}A(x)|](x_i, x_j)$, thanks to the fact that $e^{-|p|} = \int_0^\infty e^{-t-p^2/4t} dt / \sqrt{\pi t}$. Note that it was first necessary to replace the determinant by the product of its diagonal elements and then to use the diamagnetic inequality; otherwise we would have to worry about the minus signs in the determinant

Similarly, we can set $A = 0$ in the first (permanent) factor. The reason is that the permanent can only increase if we replace each matrix element by its absolute value and then replace that, in turn, by a larger number. But the diamagnetic inequality (actually, the Wiener integral representation, to be precise) tells us that this is achieved by setting $A = 0$ (even if $R_j \neq R_k$).

In this manner we obtain the upper bound

$$\int d\underline{X} d\underline{R} \frac{1}{K!} \text{perm} \left(e^{-\frac{\beta}{M} p^2}(R_j, R_k) \right) \times \frac{1}{N!} \prod_{i=1}^N \left(e^{-\beta C_3 |p|}(x_i, x_i) \right) \text{Tr}_{\mathcal{F}} e^{-\beta H_1^{\text{rad}}}(\underline{X},) . \quad (3.30)$$

The expression containing the Fock space trace still depends on the variables $\underline{X}$. Using (C.14) from Appendix C we see that

$$\ln \text{Tr}_{\mathcal{F}} e^{-\beta H_1^{\text{rad}}}(\underline{X}, \underline{R}) \leq \ln \text{Tr}_{\mathcal{F}} e^{-\beta H_f} + \frac{4\pi}{3} |\ln(1 - \varepsilon)| \Lambda^{3-3s} , \quad (3.31)$$

where ε is given in (3.21) and where (see (3.13))

$$G(y, \underline{X}) = \sum_I \Phi_I(\underline{X})^2 W_I(y) \leq 8 . \quad (3.32)$$

Inequality (3.31) is true, as shown in (C.9), (C.14) provided the criterion $M \leq \varepsilon K$ given there is satisfied. Since $G(y, \underline{X}) \leq 8$ for all $y, \underline{X}$ this criterion is satisfied with ε as in (3.21), and this can be achieved by choosing C_1 small enough.

Recalling that the operators p^2 (associated with the nuclei) and $|p| = \sqrt{p^2}$ (associated with the electrons) are Dirichlet Laplacians on the domain Ω we get the upper bound

$$\begin{aligned} \text{Tr} e^{-\beta H_3} &\leq \mathcal{Z}_{\text{nucleus}}(K) \frac{1}{N!} \left[\text{Tr} e^{-\beta \sqrt{p^2}} \right]^N \text{Tr}_{\mathcal{F}} e^{-\beta H_f} \\ &\quad \exp \left\{ \beta N (128 \Lambda^{2s} + C_1^2 + \frac{256 \alpha \mathcal{L}}{3 \sqrt{3} \pi} C_1 \Lambda^{4-3s} + \frac{4\pi}{3} |\ln(1 - \varepsilon)| \Lambda^{3-3s}) \right\} . \end{aligned} \quad (3.33)$$

This proves Lemma 3.2 □

The factor $\frac{1}{N!} \left[\text{Tr} e^{-\beta C_3 \sqrt{p^2}} \right]^N$ can be estimated from above, by the Golden-Thompson inequality, as

$$\frac{1}{N!} \left[\int_{\mathbb{R}^3} e^{-\beta C_3 |p|} dp \right]^N |\Omega|^N , \approx \exp \left\{ |\Omega| \left(-\rho_{\text{electron}} \ln(\rho_{\text{electron}}) + \rho_{\text{electron}} + \rho_{\text{electron}} \ln(8\pi \beta^{-3} C_3^{-3}) \right) \right\} \quad (3.34)$$

To prove Theorem 3.1 we have to consider numerical values for our constants. Let us collect together the conditions on them, which are (3.21), (3.24). That is

$$\varepsilon = \frac{(4096)(0.06)\pi}{3\sqrt{3}}\alpha C_1 = 149 C_1 \alpha < 1, \quad (3.35)$$

$$C_3 = C_1 - \max\left\{\frac{2}{0.032}, \pi Z\right\}\alpha = C_1 - \max\{64.5, \pi Z\}\alpha > 0. \quad (3.36)$$

This value of C_3 is to be inserted into 3.20, using (3.34) — assuming that the two conditions on C_1 , implied by (3.35) and (3.36), are satisfied. These two conditions set bounds on α and on $Z\alpha^2$. These are $(149)(64.5)\alpha^2 = 9613\alpha^2 < 1$ and $(149)\pi Z\alpha^2 = (468)Z\alpha^2 < 1$, as stated in Theorem 3.1.

The free constants to be determined are C_1 and s . The other constants ε and C_3 are in (3.21) and (3.36), respectively. The factor $128\alpha C_1 \mathcal{L}/3\sqrt{3}\pi$ in (3.20) can be replaced by $0.47/149 = 0.0032$ since $C_1\alpha < 1/149$. Our bound is then

$$-\beta f \leq \rho_{\text{electron}} \ln 2 - \beta f_{\text{nucleus}} \quad (3.37)$$

$$+ \beta \rho_{\text{electron}} \left(128\Lambda^{2s} + C_1^2 + 0.0032\Lambda^{4-3s} + \frac{4\pi}{3} |\ln(1-\varepsilon)| \Lambda^{3-3s} \right) \quad (3.38)$$

$$- \rho_{\text{electron}} \ln(\rho_{\text{electron}}) + \rho_{\text{electron}} + \rho_{\text{electron}} \ln(8\pi\beta^{-3}C_3^{-3}), \quad (3.39)$$

where $f_{\text{nucleus}} = -kT|\Omega|^{-1} \ln \mathcal{Z}_{\text{nucleus}}$ is the free energy per unit volume for non-interacting bosonic nuclei of mass mM .

If we choose, for example,

$$\varepsilon = 149 C_1 \alpha = 1 - \exp\left(\frac{-468}{1 - 468 Z\alpha^2}\right), \quad (3.40)$$

and $s = 4/5$ in order that the two largest Λ exponents in (3.38) have a common value $(8/5)$, and restrict $Z\alpha^2 \leq (\frac{39}{40})(\frac{1}{468})$, then (3.1)-(3.3) is obtained. $\square$

4 Decomposition into Boxes

In this section we shall give the details of the lower bound, (3.12), of the kinetic energy operator contained in (3.8) in terms of a Fock space energy operator. We recall the IMS localization into disjoint cubes γ_ℓ with side length Λ^{-s} and overlapping cubes Γ_ℓ with twice the side length introduced in (3.5) – (3.7).

LEMMA 4.1. *On the Hilbert space $\wedge_{i=1}^N L^2(\mathbb{R}^3; \mathbb{C}^2)$ of N electrons with 2 spin states we have that for all values of C_1 and all vector potentials $A(x)$,*

$$\sum_I \Phi_I(\underline{X}) \sum_{j=1}^N \{T_j^P(A) - C_1|p_j + \sqrt{\alpha}A(x_j)|\} \Phi_I(\underline{X}) \geq -\frac{16\alpha C_1 \mathcal{L}}{3\sqrt{3}} \sum_I \Phi_I(\underline{X})^2 \int_{\mathbb{R}^3} B(x)^2 W_I(x) dx - C_1^2 N, \quad (4.1)$$

where the function $W_I(x)$, $x \in \Omega$, is given by

$$W_I(x) = \sum_{k \in I} \chi_k(x) \leq 8, \quad (4.2)$$

where χ_k is the characteristic function of the cube Γ_k and where $k \in I = (\ell_1, \dots, \ell_N)$ means that at least one of the ℓ_i equals k . Note our convention that each χ_k is allowed to enter the sum in (4.2) at most once, i.e., if k appears 5 times in I then χ_k appears once in (4.2). The constant $\mathcal{L}$ in (4.1) is the $\gamma = 1/2$, 3-dimensional Lieb-Thirring constant; $\mathcal{L} < 0.06003$.

Note: See [7] for the value of $\mathcal{L}$ quoted above and see [18, appendix A] for the fact that it is not necessary to include an extra factor of 2 in order to account for the 2 spin states.

Proof. Fix $I = (\ell_1, \dots, \ell_N)$ and consider the single term

$$Y_I = \Phi_I(\underline{X}) \sum_{j=1}^N [T_j^P(A) - C_1|p_j + \sqrt{\alpha}A(x_j)|] \Phi_I(\underline{X}). \quad (4.3)$$

In the index set I the index k_1 appears n_1 times, the index k_2 appears n_2 times etc. where the numbers $n_i \geq 1$ and $\sum_i n_i = N$.

Our goal is to find a lower bound to $(\Psi, Y_I \Psi)$ for any Ψ in $\wedge^N L^2(\Omega; \mathbb{C}^2)$. Let us consider the first n_1 terms in (4.3), i.e., $(\Phi_I \Psi, \sum_{j=1}^{n_1} \mathcal{T}_j \Phi_I \Psi)$, where $\mathcal{T}$ is the operator appearing in [] in (4.3). In evaluating this inner product we can fix the coordinates x_j, σ_j with $j = n_1 + 1, \dots, N$ and then integrate over them at the end. In other words, the proof of our inequality (4.1) will follow from the following statement: For each $n > 1$ and each k , every normalized, antisymmetric function ψ of n space-spin variables, with support in $(\Gamma_k)^n$ satisfies the inequality

$$\frac{1}{(\psi, \psi)} (\psi, \sum_{j=1}^n \mathcal{T}_j \psi) \geq -\frac{16\alpha C_1 \mathcal{L}}{3\sqrt{3}} \int_{\Gamma_k} B(x)^2 dx - C_1^2 n. \quad (4.4)$$

By the arithmetic geometric mean inequality ($a^2 + C_1^2 \geq 2C_1\sqrt{a}$)

$$\sum_{j=1}^n \{T_j^P(A) - C_1|p_j + \sqrt{\alpha}A(x_j)|\} \geq -C_1^2n + C_1 \sum_{j=1}^n \left[2\sqrt{T_j^P(A)} - |p_j + \sqrt{\alpha}A(x_j)|\right] \quad (4.5)$$

$$\geq -C_1^2n - C_1 \text{Tr} \left[2\sqrt{T_j^P(A)} - |p + \sqrt{\alpha}A|\right]_- . \quad (4.6)$$

Here, $[x]_-$ denotes the negative part of x (which is always ≥ 0).

Using the inequality of Birman and Solomyak [1] (see also [18])

$$\text{Tr} \left[2\sqrt{T_j^P(A)} - |p + \sqrt{\alpha}A|\right]_- \leq \text{Tr} \left[4T_j^P(A) - (|p + \sqrt{\alpha}A|)^2\right]_-^{1/2} \quad (4.7)$$

$$= \text{Tr} \left[(3(p + \sqrt{\alpha}A)^2 + 4\sqrt{\alpha}\sigma \cdot B)\right]_-^{1/2} . \quad (4.8)$$

By the Lieb-Thirring inequality (but with the added remarks in [18] to avoid the factor of two) (4.8) is bounded above by

$$\frac{16\alpha\mathcal{L}}{3\sqrt{3}} \int_{\Gamma_j} B(x)^2 dx . \quad (4.9)$$

The bound $W_I(\underline{X}) \leq 8$ in (4.2) comes from the fact that a point $x \in \mathbb{R}^3$ can lie in at most 8 cubes Γ_ℓ . $\square$

5 A Simpler Theorem with a Simpler Proof

In this section we show how to obtain a lower bound on the free energy per unit volume f that is correct in all respects except that it does not vanish as $\rho \rightarrow 0$. Not only is the proof simpler but some of the constants are also better. No localization is required.

THEOREM 5.1 (Simplified lower bound on f). *Assume that $\alpha < 1/35$ and $Z\alpha^2 < (\frac{250}{320})(\frac{1}{58.5})$. (This means $Z \leq 250$ when $\alpha = 1/137$.) Then*

$$\begin{aligned} f(\beta, \rho, Z) &> -kT \{ \rho_{\text{electron}} \ln 2 + \rho_{\text{electron}} \ln(\rho_{\text{electron}}) - \rho_{\text{electron}} \} \\ &\quad - kT \rho_{\text{electron}} \ln(8\pi(kT)^3 C_3^{-3}) + f_{\text{nucleus}}(\beta, \rho_{\text{nucleus}}) , \\ &\quad - \frac{4\pi(468)(40)}{3 \cdot 70} \Lambda^3 - \left(\frac{1}{18.6\alpha} \right)^2 \rho_{\text{electron}} - 0.026\Lambda^4 , \end{aligned} \quad (5.1)$$

where f_{nucleus} is the free energy per unit volume for non-interacting bosonic nuclei of mass mM and

$$C_3\alpha = \frac{1}{18.6} - \alpha^2 \max\{64.5, \pi Z\} - \frac{1}{18.6} \exp \left\{ \frac{-58.5}{1 - 58.5 Z\alpha^2} \right\} \quad (5.2)$$

See equation (3.39) for a more general expression.

Proof. The proof is as in the proof of Theorem 3.1 except that the electrons are not localized (but they are confined to the domain Ω and the wave function satisfies Dirichlet boundary conditions on $\partial\Omega$). In other words, we eliminate Φ_I and $\sum_I$ from the equations. The localization penalty $128N\Lambda^{2s}$ is eliminated. The function $W_I(y)$ is replaced by the characteristic function of the domain Ω and (3.13) is replaced by $\int_{\mathbb{R}^3} W(y)dy = |\Omega|$ and $W(y) \leq 1$.

Expression (3.12) is replaced, therefore, by

$$- \frac{16\alpha C_1 \mathcal{L}}{3\sqrt{3}} \int_{\Omega} B(y)^2 dy - NC_1^2. \quad (3.12')$$

Thus, we save a factor of 8 because there is no longer a concern about overlapping cells Γ_ℓ .

The function $G(y, \underline{X})$ is replaced simply by the characteristic function of Ω (for all $\underline{X}$), whence $\int_{\mathbb{R}^3} G(y, \underline{X})dy = |\Omega|$. The bound (3.32) is replaced by $G(y, \underline{X}) \leq 1$. In view of this, the number ε in (3.21) and (C.10) is reduced by a factor of 8 to

$$\varepsilon' = 8\pi C_4 = 512\pi\alpha C_1 \mathcal{L}/3\sqrt{3} \quad (3.21')$$

Inequality (3.17) becomes

$$\int_{\Omega} B(y)^2 dy \leq 4 \int_{\Omega} D^*(y) \cdot D(y) dy + \frac{1}{\pi} \Lambda^4 |\Omega|. \quad (3.17')$$

Lemma 4.1 remains true, but with the obvious replacement of $\sum \Phi_I^2 \int_{\mathbb{R}^3} B^2 W_I$ by $\int_{\Omega} B^2$ in (4.1) and with (4.2) eliminated altogether.

Lemma 3.2 becomes

LEMMA 5.2.

$$\begin{aligned} \text{Tr} e^{-\beta H} &\leq Z_{\text{nucleus}}(K) \frac{1}{N!} \left[\int_{\mathbb{R}^3} e^{-\beta C_3 |p|} dp \right]^N \text{Tr}_{\mathcal{F}} e^{-\beta H_f} \times \\ &\quad \exp \left\{ \beta \left(+NC_1^2 + \frac{16\alpha C_1 \mathcal{L}}{3\sqrt{3}\pi} \Lambda^4 |\Omega| + \frac{4\pi}{3} |\ln(1 - \varepsilon')| \Lambda^3 |\Omega| \right) \right\}, \quad (5.3) \end{aligned}$$

where $Z_{\text{nucleus}}(K)$ is the partition function of K non-interacting bosons of mass M (even if some of the nuclei happen to be fermions). The number ε' (assumed to be < 1) is in (3.21') and, as in (3.36), $C_3 = C_1 - \max\{64.5, \pi Z\}\alpha > 0$.

The final task is to choose C_1 . Our conditions on ε' and on C_3 lead, as before, to conditions on α and $Z\alpha^2$, namely $(18.6)(64.5)\alpha^2 < 1$ (or $\alpha < 1/35$) and $(18.6)\pi Z\alpha^2 < 1$ (or

$Z\alpha^2 < 1/58.5$). We choose a slightly lower bound for $Z\alpha^2$, namely $Z\alpha^2 < (250/320)(1/58.5)$, and we choose

$$\varepsilon' = 18.6C_1\alpha = 1 - \exp\left(\frac{-58.5}{1 - 58.5 Z\alpha^2}\right). \quad (5.4)$$

We can bound $\frac{16\alpha C_1 \mathcal{L}}{3\sqrt{3}\pi}$ by $0.47/18.6 = (0.0032)8 = 0.026$. These choices lead to Theorem 5.1. $\square$

A The Schrödinger representation

In the proof of Lemma 3.2, especially eq. (3.27), we evaluated a trace over the full Hilbert space in the “Schrödinger representation” in which the field A is regarded as a c-number field. For a fuller discussion and justification of this method we can refer, for example, to [6, part I, sec. 2], but here we discuss only what is needed in our application.

First, we note that since the volume of the universe $|\mathcal{U}|$ is finite and there is an ultra-violet cutoff Λ , there are only finitely many photon modes that interact with the electrons and nuclei. Each mode is a harmonic oscillator mode and can be described in the usual Schrödinger representation by the canonical operators p_k and q_k , one pair for each k -value and each polarization. In our case the q_k is just the Fourier component of $A(y)$ namely $\hat{A}(k)$.

The noninteracting modes are infinite in number but they can be ignored since their contribution to the trace is easy to compute (Planck’s formula).

In evaluating the trace on the right side of (3.26) we can use the q representation for the photon modes and the x representation for the L^2 space, as usual. The operator H_1^{rel} involves the electron/nuclei p and x operators but it involves only the q_k ’s and not the p_k ’s. On the other hand, H_1^{rad} involves the p_k and q_k operators and the x operators, but it does not involve the electron/nuclei p operators.

Thus, $e^{-\beta H_1^{\text{rel}}}$ is a multiplication operator as far as the photon modes are concerned and $e^{-\beta H_1^{\text{rad}}}$ is a multiplication operator for the electron/nuclei L^2 space. In (3.27) the notation $d\underline{X} d\underline{R}$ is standard Lebesgue measure while $\mathcal{D}(A)$ means Lebesgue integration over the (finitely many) q_k ’s. It is well known that the (finite) trace of the exponentials of the operators that we are considering can be evaluated in the Schrödinger representation by taking the x, x and q, q matrix elements and integrating over these variables in this manner. Indeed, the kernel $\langle A | e^{-\beta H_1^{\text{rad}}} | A' \rangle$ is an $(\underline{X}, \underline{R})$ dependent Mehler kernel.

B A lemma about localization

LEMMA B.1 (localization and convex functions). *Let H be a self-adjoint operator on some Hilbert spaces $\mathcal{H}$ with dense domain $D(H)$. Let $\Phi_j, j = 1, \dots, M$ be a collection of bounded operators such that Φ_j maps $D(H)$ to itself and such that*

$$\sum_{j=1}^M \Phi_j^* \Phi_j = I \quad (\text{B.1})$$

Then, for any convex function $f(x)$ and any normalized $\Psi \in D(H)$, we have that

$$\sum_{j=1}^M (\Phi_j \Psi, f(H) \Phi_j \Psi) \geq f \left(\sum_{j=1}^M (\Phi_j \Psi, H \Phi_j \Psi) \right). \quad (\text{B.2})$$

If we also assume that $\sum_{j=1}^M \Phi_j \Phi_j^* = I$ and that $f(H)$ is trace class, then

$$\text{Tr} f(H) \geq \text{Tr} f \left(\sum_{j=1}^M \Phi_j^* H \Phi_j \right). \quad (\text{B.3})$$

Proof. Note that

$$\begin{aligned} \sum_{j=1}^M (\Phi_j \Psi, f(H) \Phi_j \Psi) &= \sum_{j=1}^M \frac{(\Phi_j \Psi, f(H) \Phi_j \Psi)}{(\Phi_j \Psi, \Phi_j \Psi)} (\Phi_j \Psi, \Phi_j \Psi) \\ &\geq \sum_{j=1}^M f \left(\frac{(\Phi_j \Psi, H \Phi_j \Psi)}{(\Phi_j \Psi, \Phi_j \Psi)} \right) (\Phi_j \Psi, \Phi_j \Psi), \end{aligned} \quad (\text{B.4})$$

by applying Jensen's inequality in the spectral representation of H . With $c_j = \|\Phi_j \Psi\|^2$, we have that $\sum_{j=1}^M c_j = \|\Psi\|^2 = 1$, and hence we may apply Jensen's inequality once more to obtain

$$\sum_{j=1}^M f \left(\frac{(\Phi_j \Psi, H \Phi_j \Psi)}{(\Phi_j \Psi, \Phi_j \Psi)} \right) (\Phi_j \Psi, \Phi_j \Psi) \geq f \left(\sum_{j=1}^M (\Phi_j \Psi, H \Phi_j \Psi) \right). \quad (\text{B.5})$$

This proves (B.2). To prove (B.3) we just sum (B.2) over the orthonormal basis $\{\psi_n\}$ of eigenfunctions of $\sum_{j=1}^M \Phi_j^* H \Phi_j$ and obtain

$$\begin{aligned} \text{Tr} f \left(\sum_{j=1}^M \Phi_j^* H \Phi_j \right) &= \sum_n f \left(\left(\psi_n, \sum_{j=1}^M \Phi_j^* H \Phi_j \psi_n \right) \right) = \sum_n f \left(\sum_{j=1}^M (\Phi_j \psi_n, H \Phi_j \psi_n) \right) \\ &\leq \sum_n \sum_{j=1}^M (\Phi_j \psi_n, f(H) \Phi_j \psi_n) = \text{Tr} \sum_{j=1}^M \Phi_j^* f(H) \Phi_j = \text{Tr} \sum_{j=1}^M f(H) \Phi_j \Phi_j^* = \text{Tr} f(H). \end{aligned} \quad (\text{B.6})$$

C Perturbed black-body radiation

One of the problems in section 3 is to estimate the partition function of the Hamiltonian H_1^{rad} (see (3.19)) in terms of the partition function of the universe, $\mathcal{U}$, with an error term that depends only on the number of electrons and nuclei and, possibly, on the ultraviolet cutoff.

In general, let us consider a Hamiltonian on Fock space of the form

$$H_M = \hbar c \sum_{k,k'} \{ \delta_{k,k'} \delta^{i,j} |k| - M_{k,k'}^{i,j} \} a_i^*(k) a_j(k) , \quad (\text{C.1})$$

with M self adjoint, i.e. $M_{k,k'}^{i,j} = \overline{M_{k',k}^{j,i}}$. Recall that $k = \frac{2\pi}{L}(n_1, n_2, n_3)$ with n_i an integer (but $k = 0$ is omitted) and $i, j \in \{1, 2, 3\}$. The volume of $\mathcal{U}$ is L^3 .

The matrix $\{\cdot\}$ appearing in (C.1), can be written, in an obvious notation, as $K - M$.

Later on we shall present the M we are interested in for the purposes of this paper, but for the moment let us consider the partition function

$$\ln \mathcal{Z}_M = \ln \text{Tr}_{\mathcal{F}} e^{-\beta H_M} = - \sum_j \ln(1 - e^{-\beta \lambda_j}) = - \text{Tr} \ln \{1 - e^{-\beta(K-M)}\} , \quad (\text{C.2})$$

where the λ_j are the eigenvalues of the matrix $K - M$. In order to make sense of $\mathcal{Z}_M$ we require the eigenvalues of $K - M$ to be all positive.

We want to find an upper bound to $\ln \mathcal{Z}_M - \ln \mathcal{Z}_0$. Our main result here is the following. (Remark: Notice that there is no β in (C.3)).

LEMMA C.1. *Assume that $0 \leq M < \varepsilon K$ with $0 < \varepsilon < 1$. Then*

$$\ln \mathcal{Z}_M - \ln \mathcal{Z}_0 \leq \int_0^1 \text{Tr}((K - sM)^{-1} M) ds = \text{Tr} \ln(K) - \text{Tr} \ln(K - M) \leq \left| \frac{\ln(1 - \varepsilon)}{\varepsilon} \right| \text{Tr}(K^{-1} M) . \quad (\text{C.3})$$

Proof. We write the difference on the left side of (C.3) as

$$\int_0^1 \frac{d}{ds} [-\text{Tr} \ln(1 - e^{-\beta(K-sM)})] ds = \int_0^1 \beta \text{Tr} \frac{1}{e^{\beta(K-sM)} - 1} M ds \leq \int_0^1 \text{Tr} \frac{1}{(K - sM)} M ds \quad (\text{C.4})$$

since $(e^x - 1)^{-1} < x^{-1}$ for $x > 0$ and since M is positive semidefinite. The estimate on the right side of (C.3) follows by substituting $M < \varepsilon K$ in the denominator of the last expression in (C.4) and using the fact that x^{-1} is matrix monotone for $x > 0$. Finally, doing the s integral we obtain the inequality in (C.3). $\square$

We now apply this lemma to the operator H_1^{rad} in (3.19). The matrix $M \geq 0$ is given by

$$M_{k,k'}^{i,j} = \frac{C_4}{(2\pi)^2} \left(\frac{2\pi}{L} \right)^3 \widehat{\chi}(k) \widehat{\chi}(k') |k|^{1/2} |k'|^{1/2} \widehat{G}(k-k', \underline{X}) \left[\delta^{i,j} + \frac{(k \cdot k')(k_i k'_j)}{|k|^2 |k'|^2} - \frac{k'_i k'_j}{|k'|^2} - \frac{k_i k_j}{|k|^2} \right], \quad (\text{C.5})$$

with $C_4 = 64\alpha C_1 \mathcal{L}/3\sqrt{3}$ and where $\widehat{G}(k, \underline{X}) = \int_{\mathbb{R}^3} e^{iy \cdot k} G(y, \underline{X}) dy$ with $G(y, \underline{X})$ given in (3.32). (Here, $\underline{X}$ merely plays the role of a parameter). First, we note that, as matrices, $M \leq N$ where

$$N_{k,k'}^{i,j} = \frac{C_4}{\pi^2} \delta^{i,j} \left(\frac{2\pi}{L} \right)^3 \widehat{\chi}(k) \widehat{\chi}(k') |k|^{1/2} |k'|^{1/2} \widehat{G}(k-k', \underline{X}). \quad (\text{C.6})$$

The requirement that $N \leq \varepsilon K$, as a matrix, is equivalent to the requirement that $K^{-1/2} N K^{-1/2} \leq \varepsilon I$. Hence, we need to show that

$$\frac{C_4}{\pi^2} \left(\frac{2\pi}{L} \right)^3 \sum_{k,k'} \widehat{G}(k-k', \underline{X}) \widehat{\chi}(k) \bar{f}(k) \widehat{\chi}(k') f(k') \leq \varepsilon \sum_k |f(k)|^2, \quad (\text{C.7})$$

for all functions $f(k)$. The inequality

$$\frac{C_4}{\pi^2} \left(\frac{2\pi}{L} \right)^3 \sum_{k,k'} \widehat{G}(k-k', \underline{X}) \bar{f}(k) f(k') \leq \varepsilon \sum_k |f(k)|^2, \quad (\text{C.8})$$

would clearly imply (C.7), and this is implied by

$$\begin{aligned} & \frac{C_4}{\pi^2} \left(\frac{2\pi}{L} \right)^3 \int_{\mathbb{R}^3} G(y, \underline{X}) \left| \sum_k e^{-iy \cdot k} f(k) \right|^2 dy \\ & \leq \frac{C_4}{\pi^2} \sup_{y, \underline{X}} G(y, \underline{X}) \left(\frac{2\pi}{L} \right)^3 \int_{\mathbb{R}^3} \left| \sum_k e^{-iy \cdot k} f(k) \right|^2 dy = 8\pi C_4 \sup_{y, \underline{X}} G(y, \underline{X}) \sum_k |f(k)|^2. \end{aligned} \quad (\text{C.9})$$

Thus, the condition $8\pi C_4 \sup_{y, \underline{X}} G(y, \underline{X}) \leq \varepsilon$ guarantees that $M \leq \varepsilon K$. If we take

$$\varepsilon = 64\pi C_4 = 4096 \pi \alpha C_1 \mathcal{L}/3\sqrt{3}, \quad (\text{C.10})$$

and use the fact that $G(y, \underline{X}) \leq 8$, the condition is satisfied.

It remains to apply the lemma above to this particular choice of M , which (recalling (3.13)) yields the bound

$$\ln \mathcal{Z}_M - \ln \mathcal{Z}_0 \leq 8\pi C_4 \left| \frac{\ln(1-\varepsilon)}{\varepsilon} \right| \left(\frac{2\pi}{L} \right)^3 \sum_k \widehat{\chi}_\Lambda(k)^2 \int_{\mathbb{R}^3} G(y, \underline{X}) dy \quad (\text{C.11})$$

$$\approx 8\pi C_4 \left| \frac{\ln(1-\varepsilon)}{\varepsilon} \right| \int_{\mathbb{R}^3} \widehat{\chi}_\Lambda(k)^2 dk \int_{\mathbb{R}^3} G(y, \underline{X}) dy \quad (\text{C.12})$$

$$\leq \frac{32\pi^2 C_4}{3} \left| \frac{\ln(1-\varepsilon)}{\varepsilon} \right| \Lambda^3 \int_{\mathbb{R}^3} G(y, \underline{X}) dy \quad (\text{C.13})$$

$$= \frac{4\pi}{3} |\ln(1-\varepsilon)| \Lambda^{3-3s} N, \quad (\text{C.14})$$

as used in (3.31).
